Lab 2 - Machine Learning for Social Science

To be handed in no later than September 3rd, 10:00. The submission should include code, relevant output, as well as answers to questions. We recommend the use of RMarkdown to create the report.

Part 1: Social Network Ad Purchase (cont.)

In the first part of this lab, we will again consider the *ad purchase* data that we used in lab 1 (containing information about individuals' purchasing behavior under exposure to online ads). As in lab 1, we will build classification models to predict ad purchase (0/1) based on a set of covariates about individuals (including Age, Gender and Salary). In contrast to lab 1, we here focus on *non-parametric methods*.

- 1. Begin by importing the file "Kaggle_Social_Network_Ads.csv". Format the outcome variable Purchased as a factor variable (this is required for the subsequent analysis using the caret package). You may also delete the user_id column, as it will not be used.
- 2. The first non-parametric method you will use to predict ad purchase is the k-nearest neighbors algorithm. As we talked about in the lecture, it has one key parameter, k, that the researcher must set. Use the caret package to implement a 10-fold cross-validation procedure that examines the test accuracy of kNN under different choices of k (hint 1: set method="knn" to estimate a kNN with caret| hint 2: use the tuneGrid argument to specify your grid of k values). Consider the following values of k: {1,2,3,4,5,6,7,8,9,10,15,20,25,50}. Because kNN is sensitive to the scale of variables, we must standardize our variables prior to estimation (hint: you can add the following argument to train(): preProcess=c("center", "scale"), to do so). From the results, plot the test accuracy against k (hint: results can be extracted from the train object by using \$results). Interpret this plot. How does the performance—for the best k—compare to that of GAM and standard linear regression (i.e., your results in lab 1)? Which do you prefer? Why?
- 3. Suppose we now learn that those who collected the data have retrieved some additional information (in the form of digital traces) about these 400 individuals. This extra information consists of 20 variables X_1, X_2, \ldots, X_{20} . The people providing us with the data suggest that *some* of these variables could be very relevant for predicting Purchase, but they also note that many of them likely are irrelevant. The problem is, they do not know which is which. This new data set is stored in the .csv file "Kaggle_Social_Network_Ads_Augmented.csv". Import it to R and process it the same way you did in #1.
- 4. Repeat task #2 for this new data set (from step #3). How does the prediction accuracy change? How do you explain this difference (or lack thereof)?
- 5. Motivated by the results obtained in #4, we want to explore an alternative method. Based on the properties—which we discussed in the lecture—of *decision trees*, do you think it has the potential to perform better than kNN on the data set from #3? If yes, why?
- 6. Estimating decision trees is what you will do now. In R, we can use the package rpart for this. Decision trees have two main parameters that a researcher must choose prior to estimation: (i) the minimum number of observation in each leaf node (in rpart: minbucket), and (ii) the complexity parameter α (in rpart: cp). In practice, the former is often set heuristically (using some rule-of-thumb) and the latter using cross-validation. Please do the following:

- a. Answer why it generally is *not* a good idea to set minbucket to either a *very large* number or a *very small* number (relative to the size of your data).
- b. Use the caret package (method="rpart") to implement a 10-fold cross-validation procedure to assess how the test accuracy changes as a function of the complexity parameter (ISL: α; rpart: cp). Hint: use the tuneGrid argument to specify your grid of cp values. Consider the following values for cp: {0,0.01,0.025,0.05,0.10,0.25,0.5,1.0}. (note: minbucket is here set to a default value=10). Plot the test accuracy against cp (hint: extract results as you did in #2 and #3). Interpret this plot. How does the accuracy for the best cp compare to kNN? What do you attribute this difference to?
- c. Use the rpart.plot package to plot the decision tree you found to be the best in b (hint: you can extract the model with the highest accuracy from a caret model using finalModel). First report how many *internal* and *terminal* nodes this tree has. Then, provide a interpretation. Does any of the "new" variables (X_1, \ldots, X_{20}) show up in the tree?
- d. Use caret's varImp() function to calculate variable importance scores. Interpret.

Part 2: Bernie Sanders and Donald Trump tweets (cont.)

In the second part of this lab, we will reconsider the *Bernie vs. Trump* twitter data set that we used in lab 1. As in lab 1, we shall build classification models to predict who authored a given tweet based on its linguistic content, and to identify which words are the most discriminative between Bernie and Trump.

- 1. Import the file "trumpbernie2.csv" to R (note: to reduce computational time, I have reduced the number of columns for this lab), and format the outcome variable trump_tweet as a factor variable (again, this is needed for the caret package to recognize it as a discrete variable.)
- 2. Use caret to implement a 5-fold cross-validation procedure that estimates the test error for a decision tree with different cp (ISL: α) values. Consider the following cp values: {0,0.001,0.01,0.1,0.25}. Report the accuracy of the best configuration. How does this compare to the performance of a standard logistic regression (LR) and a ridge regression (RR)? You do not need to estimate the LR and the RR yourself—I provide their performance here: Accuracy(LR)=55%. Accuracy(RR)=86%. Why do think this is the case? Doing the following two things might help you answer this question:
 - a. Plot the tree which achieved the highest test accuracy (hint: again, you can extract the best model using \$finalModel, and plot it using rpart.plot). Is it a big or a small tree?
 - b. Calculate variable importance. How many variables have non-zero values?
- 3. Given the results in #2, we want to explore other alternative methods. Using once again the caret package, you shall now implement a 5-fold cross-validation procedure that fits a random forest model (method="rf") with different mtry values. mtry controls the number of variables that are considered at each split (corresponding to parameter m in ISL). Specifically, you shall consider the following values for mtry: {1,5,10,25,50,200} (hint: again, you specify this grid using the argument tuneGrid). Another important parameter of random forest models is the number of trees to use. Here you shall use 200 (hint: you may enter ntree=200 as an argument in train() to do so). The estimation may take a couple of minutes to finish. Once it has finished, please do the following:
 - a. Plot accuracy against mtry. Interpret this plot. Does decorrelating the trees seem to help performance?
 - b. Relate the performance of the best random forest model to the best decision tree model. Do you find a meaningful improvement using random forest? Why do you think that is (or isn't)? Examining the variable importance scores may provide some clues; how many non-zero variables do you find for the random forest?

- c. Relate the performance of the best random forest model and the ridge regression from #2. What do you think this difference indicates about the data, and more specifically the relation ship between X and y?
- d. Consider the variable importance scores in a bit more detail: does the variables that appear in the top 20 align with your expectations? Note that variable importance does not reveal the direction; e.g., whether a certain word is associated with Trump or with Bernie. For this, we can use the randomForest's function plotPartial() which produces a partial dependence plot for a variable of choice. Select three variables (words) which you find interesting, and create three separate partial dependency plot. In order to interpret the y-axis of the plot, use the argument which.class to specify which class ("0" or "1") should represent the positive class.

Quiz wrap-up:

Provided here are three optional wrap-up questions that help recap some central ideas from the lecture, and which are taken from old exams.

- 1. For which of the following supervised learning methods does standardizing your input data (X) influence the predictions?
 - a. Decision tree
 - b. Lasso
 - c. kNN
 - d. Standard OLS
- 2. Which among the following are important aspects distinguishing *parametric* and *non-parametric* supervised learning models?
 - a. Non-parametric methods make strong assumptions about the functional form of models; parametric methods do not.
 - b. Parametric methods make strong assumptions about the functional form of models; non-parametric methods do not.
 - c. Parametric methods are generally more appropriate for *inference* tasks compared to non-parametric methods.
 - d. Non-parametric methods are generally more appropriate for *inference* tasks compared to parametric methods.
- 3. In terms of the bias-variance decomposition, a decision tree with 20 leaves tends to have than a decision tree with 3 leaves.
 - a. higher variance and lower bias.
 - b. higher variance and higher bias.
 - c. lower variance and lower bias.
 - d. lower variance and higher bias.
